Description

Improved Apparatus for Electrically Mediated Delivery of Therapeutic Agents

5 Technical Field

The present invention is directed to an apparatus for delivery of prophylactic and therapeutic agents to patients. In particular, the apparatus is designed to achieve safe, reproducible, efficacious, and cost effective delivery of prophylactic and therapeutic agents.

10 Background of the Invention

Prophylactic and therapeutic agents have long been delivered to patients using various conventional routes of administration, such as topical, oral, intravenous, parenteral, and the like. Once administered to the patient by the selected route, the delivery of the agent to the tissue of interest and its beneficial interaction with the tissue is largely dependent on its inherent
15 physicochemical factors, but may have been facilitated by, for example, selected components of the delivery composition such as carriers, adjuvants, buffers and excipients, and the like.

More recently, the application of electrical signals has been shown to enhance the movement and uptake of macromolecules in living tissue. Application of such electrical signals in tissue relative to the administration of a prophylactic or therapeutic agent can have desirable
20 effects on the tissue and/or the agent to be delivered. Specifically, techniques such as electroporation and iontophoresis have been utilized to enhance the delivery and/or uptake of a variety of agents in tissue. Such agents include pharmaceuticals, proteins, antibodies, and nucleic acids. Potential clinical applications of such techniques include the delivery of chemotherapeutic drugs and/or therapeutic genes in tumors, the delivery of DNA vaccines for
25 prophylactic and therapeutic immunization, and the delivery of nucleic acid sequences encoding therapeutic proteins.

Many devices have been described for the application of electrical signals in tissue for the purpose of enhancing agent delivery. The vast majority of these have focused on a means for effective application of the electrical signals within a target region of tissue. A variety of surface
30 and penetrating electrode systems have been developed for generating the desired electrophysiological effects.

In spite of the promise associated with electrically mediated agent delivery and the potential clinical applications of these techniques, progress has been hampered by the lack of an

effective means to achieve the overall objective of efficient and reliable agent delivery using these techniques. Significant shortcomings of current systems include a complex application procedure, unwieldy device design, potential hazards for the user and patient and the inability to provide a cost effective means for administration.

- 5 Given that safe, effective, consistent, and cost effective means for the administration of therapeutic agents are highly desirable, the development of improved application systems is well warranted. Such development should include a means for minimizing operator-associated variability and ensuring the safety of the user and the patient while providing for accommodating the differences in patient characteristics likely to be encountered during widespread clinical
- 10 application of electrically mediated agent delivery.

Disclosure of the Invention

The present invention provides an integrated apparatus enabling Electrically Mediated Therapeutic Agent Delivery (EMTAD) to be accomplished in a safe, consistent, and cost effective manner. The present invention allows effective intramuscular, intradermal, and/or
5 subcutaneous administration of therapeutic or prophylactic agents such as nucleic acids, drugs, antibodies, and proteins.

In one aspect, the present invention provides an apparatus for the delivery of a therapeutic agent and electrical fields to a predetermined site within the skin and/or skeletal muscle of a patient in a manner that is effective, reproducible, and safe for both the operator and
10 the patient. The apparatus comprises a single use subassembly "cartridge" and a hand-held "applicator". The single use sub-assembly integrates a reservoir containing the agent of interest, at least one orifice through which the agent is delivered to the patient, and two or more electrodes capable of propagating electrical fields within the tissue. The hand-held applicator interfaces with the single use cartridge and incorporates automated mechanisms to (1) deploy the
15 electrodes to the target tissue site, (2) position the orifice relative to the target tissue site, (3) transfer the agent from the reservoir through the orifice and into the target tissue site, and (4) relay electrical signals from a suitable pulse generator to the electrodes.

Other aspects of the invention include means for priming the automated mechanisms incorporated in the applicator upon insertion of the cartridge, identifying the model or type of
20 cartridge that has been inserted, and protecting the user and patient from accidental injury associated with the usage of the device.

Brief Description of the Drawings

Detailed Description of the Invention

Device Description

The present invention provides an improved apparatus for safe, efficacious and reproducible, transcutaneous intramuscular (IM) delivery of therapeutic agents with Electrically Mediated Therapeutic Agent Delivery (EMTAD).

A specific embodiment of an integrated unit for transcutaneous IM applications is illustrated in Figures 1-5. The apparatus consists of a main unit (applicator) 100 and a separable single use sub-assembly (cartridge) 200. The cartridge includes a reservoir to contain the agent to be administered prior to delivery. The reservoir will be designed and constructed to maintain the agent in a stable environment and prevent contamination. The reservoir is operatively connected to an orifice through which the agent is administered into the patient. Most commonly, the reservoir and orifice are comprised of a syringe connected to a hollow injection needle 300. The cartridge encloses the electrode array and includes integral automatic protection against unwanted contact with the electrodes and/or the orifice/injection needle (i.e. "stick protection").

The applicator 100 incorporates a spring mechanism for automatic insertion of the electrode array and the injection needle into the target tissue. The applicator also includes a separate spring mechanism for automated controlled therapeutic agent injection through the incorporated syringe. The applicator incorporates a means to allow electrical communication with a suitable pulse generation device capable of controlling the treatment application sequence. Most commonly electrical communication is achieved through a conductive cable and connector. A trigger 101 on the applicator is utilized to initiate the treatment. Finally a system for identifying the inserted cartridge and setting the treatment parameters based on the cartridge is provided in the applicator.

Integration of agent/syringe with cartridge

In previously disclosed devices of this nature, a means for administration of the therapeutic agent comprising a reservoir and at least one orifice through which the agent is administered have been described. In clinical practice of the previously disclosed invention it is desirable to integrate the means for administration of the therapeutic agent (reservoir and orifice) with the cartridge. Integrating the administration means with the cartridge can simplify the procedure by reducing device handling. Reducing device handling can also improve operator

and patient safety by eliminating needle stick hazards and dosage errors. Integration also improves the accuracy of the predetermined spatial relationship between the agent delivery orifice and the electrode array.

- There are several suitable embodiments of integrating the means of agent administration with the single use cartridge. The cartridge can be configured to accept a syringe and needle as the reservoir and orifice. It is desirable that once the syringe has been integrated with the cartridge that the integration is permanent. Permanent integration will prevent disassociation of the syringe and cartridge and reduce the possibility of needle stick injuries. The syringe can be an off-the-shelf syringe that is loaded with the agent prior to the agent administration procedure.
- Utilization of an off-the-shelf syringe allows one cartridge configuration to deliver numerous agent and dosage combinations. Additionally off-the-shelf syringes are readily available and cost effective. The syringe can alternatively be pre-filled with an agent and packaged with the cartridge. Utilization of a pre-filled syringe reduces the possibility for dosage errors. Additionally a pre-filled syringe does not require a plunger extending from the proximal end of the syringe to manually load the agent. Elimination of the plunger extension allows for a smaller device that uses less material and is more ergonomic.

- Another embodiment of integrating the reservoir and orifice with the cartridge is to incorporate the reservoir into the cartridge design thus eliminating the need for a separate syringe. It is preferable that the cartridge be constructed of an inert material to prevent reaction with the agent. Suitable materials include but are not limited to glass and polyethylene.
- It is desirable to store certain agents in a lyophilized state to improve shelf life. Such agents are mixed with a diluent prior to administration. A dual chamber reservoir where the lyophilized agent and the diluent are stored in the separate chambers can be utilized for such agents. Prior to treatment the separation between the chambers is removed or broken to allow mixing of the agent and diluent. One suitable separation between the chambers is a stopcock valve that is manually opened. Another suitable separation is a thin film or a check valve that can be opened when adequate pressure is applied to the diluent chamber. Such a dual chamber reservoir can be incorporated into the cartridge.

- A specific embodiment for integrating the means for agent administration with the cartridge is herein described. The specific embodiment utilizes an off-the-shelf syringe and needle 300 for the administration reservoir and orifice. The cartridge 200 is configured to accept the syringe and locate the needle orifice in a predetermined spatial relationship with the electrode

array. Furthermore the cartridge is configured with snap tabs 224 that lock the syringe in place once it is inserted into the cartridge.

Drive Mechanisms

5 There are several mechanisms that are suitable to insert the electrodes and injection needle through the skin and into the targeted treatment tissue and also to inject the agent through the needle. A compressed gas powered mechanism is one such apparatus. Electro/mechanical mechanisms such as solenoids, linear motors and lead screws are also acceptable. However the preferred approach for transcutaneous electrode and injection needle insertion is the spring-based
10 mechanism.

 Electrode insertion mechanisms require sufficient force to rapidly penetrate the skin and implant the electrodes into the muscle. Rapid insertion can reduce tenting of the skin at the insertion site and thereby reduce deflection of the electrode or needle. Electrode deflection may distort the electrode array and effect treatment efficacy and patient safety. Needle distortion may
15 effect co-localization of the agent and electrical fields. So it is desirable to insert the electrodes and needle rapidly to minimize deflection. Additionally rapid electrode/needle insertion reduces patient discomfort. The energy storage and discharge characteristics of spring-based mechanisms are well suited to enable rapid deployment of electrodes and injection needles into tissue with minimal distortion.

20 Insertion and injection mechanisms for transcutaneous applications also require sufficient linear motion (throw) to implant the electrodes to the target treatment depth and to inject the prescribed volume / dose of agent. Spring mechanisms are preferred since they can achieve adequate linear motion in a small and lightweight package. Additionally springs mechanisms do not require electrical or gas connections, they do not require consumables such as compressed
25 gas canisters and finally they are cost effective.

Automatic/Passive Spring Priming

 Although their functional characteristics and cost effectiveness make them preferable overall, spring mechanisms require priming. Energy is be imparted to and stored in the spring
30 prior to actuating the treatment sequence. Previously disclosed devices of this nature require that the user actively perform a separate step to prime the spring mechanism prior to the use of the device. The disclosed invention includes means to automatically or passively prime the spring

mechanism upon insertion of the cartridge 200 into the applicator 100. It is desirable that the priming of the spring mechanism ("spring priming") be accomplished in conjunction with the insertion of the cartridge 200 into the applicator 100. In addition to simplifying the procedure, automated/passive spring priming also eliminates the problematic failure mode of not priming the spring. A variety of energized mechanisms can be employed in the device to accomplish automated spring priming. These mechanisms comprise an energy source, a suitable trigger, and a means to transfer energy from the energy source to the spring(s). Insertion of the cartridge into the applicator activates the trigger leading to the transfer of energy from the energy source to the spring(s). Sources of energy/mechanisms to achieve this function include but are not limited to compressed gas, solenoids and electrical motor-based mechanisms.

A preferred method and apparatus is to utilize the insertion and attachment of the cartridge 200 to the applicator 100 as a means to passively prime the spring mechanisms during cartridge insertion into the applicator – "cartridge priming". Utilizing the cartridge priming method provides the benefits of the described invention while eliminating the need for the additional priming mechanism required for automated spring priming. This simplifies the device and reduces cost without sacrificing ease-of-use and safety.

In embodiments where the cartridge is utilized to prime spring drive mechanisms, there will be means to apply force to the injection drive mechanism through the cartridge without depressing the spring plunger and ejecting the agent from the syringe. Additionally, since the operator applies force to the cartridge to prime the spring mechanisms, it is desirable that the device include means to prevent accidental deployment of electrodes and/or needles during the insertion of the cartridge into the applicator to prevent needle stick injuries. Moreover it is desirable that the means for stick prevention also prevent damage and/or contamination to the electrodes and needle during priming. Finally, in such an embodiment there is a risk that the operator may release the cartridge before completing priming. This may result in the stored spring energy ejecting the cartridge from the applicator causing injury and/or damage to the device. Therefore it is desirable to prevent accidental ejection of the cartridge.

One specific embodiment is presented in Figures 1-5 for achieving the invention of cartridge priming. Those skilled in the art will appreciate that the specific mechanisms used to achieve cartridge priming are a matter of convenience and that the use of alternative mechanisms for achieving cartridge priming does not depart from the scope of the described invention. In the specific embodiment described herein, the cartridge 200 and applicator 100 are configured so

that the cartridge 200 can only be inserted into the applicator 100 in a specific priming orientation. In the priming orientation, at least one cantilevered extension 202 of the cartridge engages the injection drive mechanism 110 and imparts the priming force to the mechanism while preventing the mechanism from contacting the syringe plunger 302. This specific

5 embodiment provides stick prevention and protects the electrodes/needle from damage/contamination during priming by maintaining the electrodes/needle safely retracted and locked within the cartridge. Snap tabs 222 incorporated into the cartridge prevent the electrode hub 220 from moving axially relative to the cartridge collar 210 and thereby maintain the electrodes/needle safely retracted within the cartridge. Further stick and contamination

10 protection is provided by a cap 230 over the distal end of the cartridge. The cap 230 is removed prior to treatment application. Preferably, the cap is constructed of puncture resistant material and the interface between the cap and the cartridge is designed to minimize the risk of contamination during handling. The electrode hub 220 engages the insertion drive mechanism 120 and transfers the priming force applied to the cartridge collar 210 to the insertion

15 mechanism. To prevent accidental ejection of the cartridge during priming, this specific embodiment incorporates one-way leaf-spring latches 130 in the applicator that allow the cartridge to be inserted in the priming orientation but prevent it from being removed or ejected in that orientation. A ratchet mechanism is another suitable means to prevent accidental ejection of the cartridge. When the cartridge is completely inserted into the applicator, two spring-actuated

20 latches 112, 122 capture the insertion and injection spring mechanisms and maintain them in their primed and energized state until they are actuated during treatment. A solenoid actuator 114, 124 is attached to each latch 112, 122 and when activated displaces the latch and releases the spring mechanism 110, 120.

Upon completion of the cartridge insertion and spring mechanism priming, the cartridge

25 is twisted $\frac{1}{4}$ turn to complete attachment of the cartridge to the applicator. In this attached orientation the cantilevered extension 202 disengages from the injection drive mechanism 110 freeing the mechanism to act upon the syringe plunger 302 when the injection mechanism is released. Additionally in this attached orientation the applicator depresses the tabs 222 and frees the electrode hub to move axially relative to the cartridge, so the insertion mechanism can

30 advance the electrodes and needle when the mechanism is released.

Designs Enabling Improved Human Factors

In the practice of the invention, ergonomics and human factors play a significant role in consistently providing safe and effective agent administration. The size and shape of the device used for agent administration can affect the operator's ability to effectively deliver the agent to the target tissue site. It is desirable that the design of the device facilitate accurate positioning of the device in the proper location and orientation. Improper positioning of the device can affect both the safety and efficacy of the treatment.

In addition to the human factors associated with the user, the size and shape of the device can also influence patient acceptance. A device can be threatening to patients, particularly if it is especially large, has a form suggestive of a weapon, or is otherwise intimidating. Therefore it is desirable that the device has a form factor that is both ergonomic and non-threatening. In previously disclosed devices of this nature, the drive mechanisms have been arranged co-linearly and in series with the cartridge. This results in a long and unwieldy device. The described invention utilizes one or more drive mechanisms arranged in parallel with the cartridge and the line of action of the electrodes and syringe. The parallel drive mechanisms can be arranged co-linearly or in an offset fashion. This parallel arrangement yields a more compact, ergonomic and non-threatening device.

One specific embodiment employing offset parallel spring mechanisms is described in Figures 1-5, however, the invention can be adapted to achieve a desirable form factor utilizing other spring and drive mechanisms. For instance the spring may surround the electrode array or syringe. Additionally the mechanism may utilize mechanical advantage to increase linear motion or force.

In the specific embodiment illustrated in Figures 1-5, the insertion and injection spring mechanisms are positioned within the applicator parallel and offset from the cartridge. The Force and motion of the spring mechanisms is transferred to the cartridge through drive arms 116, 126 that extend through the applicator and interface with the cartridge.

Cartridge Identification

In order to be well suited for use in clinical applications, an EMTAD device should accommodate the range of doses that may be prescribed for a given agent. When employing EMTAD, the "dose" of the agent is determined by the volume and concentration administered, the electrode array configuration and the electrical signal parameters applied to the tissue

(including waveform, voltage, duration, frequency, and number of pulses). In order to assure that the prescribed "dose" is applied to a given patient, the proper electrical signal parameters will be conveyed to the pulse generator. Although this can be accomplished through user input, such a system would carry a risk that a user error could result in a hazardous operating condition.

- 5 Therefore it is desirable to provide an automated means for dosage recognition that minimizes the risk of a hazardous operating condition.

Although there are several automated means for dosage recognition a preferable method is accomplished in conjunction with the insertion of the cartridge into the applicator. In such an embodiment the electrical signal parameters partially determine dose are determined by the
 10 cartridge that includes the other two dose parameters (agent and electrode array). It is also desirable that the treatment sequence cannot be initiated until the electrical signal parameters are set. This assures safe and proper attachment of the cartridge to the applicator. In previously disclosed devices of this nature, programmable integrated circuits and other relatively expensive means have been described. In order to be well suited for commercial application the means for
 15 cartridge identification / electrical signal parameter recognition should be cost effective. In particular the components of the identification system and the associated manufacturing processes that are part of the single-use cartridge should be cost effective.

One skilled in the art will recognize that there are several suitable means for cartridge identification / electrical signal recognition. Suitable means include optical bar code
 20 identification and wireless radio frequency identification. In the case of bar code identification the bar code would be affixed or imprinted onto the cartridge and the reader would be integrated into the applicator. In the case of radio frequency identification the transponder would be integrated into the cartridge and the receiver would be included in the applicator. Preferably the receiver would be tuned only to receive the radio frequency signal when the cartridge was
 25 properly attached to the applicator. Another suitable method is to utilize a series of discrete switches in the applicator that may be closed when the cartridge is inserted. The pattern of open and closed switches would determine the electrical signal parameters. The switches could be electro/mechanical, opto/electro or any other suitable switch.

For example one embodiment utilizing three open contact pairs in the applicator 100 is
 30 illustrated. Conductive tape is affixed to the cartridge 200 to close the contact pairs when the cartridge is attached to the applicator. This 3-bit system will identify seven electrical signal parameter settings plus three open contact pairs will indicate when a cartridge is not attached.

In addition to defining the administration dose, the described invention would also facilitate the use of a single application system for delivery of multiple classes of agents, which require different electrical conditions to achieve effective delivery.

5 Adjustable Treatment Depth

Efficacious, consistent, and safe application of EMTAD for intramuscular delivery relies in part on treating a consistent volume of muscle tissue. However, there is a significant variation between patients and treatment sites in the subcutaneous fat pad thickness that is penetrated to access the targeted muscle tissue. In one study, (Poland GA, Borrud A, Jacobson
 10 RM, McDermott K, Wollan PC, Brakke D, Charboneau JW. Determination of deltoid fat pad thickness. Implications for needle length in adult immunization. JAMA. 1997 Jun 4;277(21):1709-11) a range of deltoid fat pad thickness from 3.7mm to 35.6mm is reported. So for a given electrode array size, the volume of muscle tissue affected will vary depending on the fat pad thickness. Additionally the thickness of tissue between the skin and the bone also vary
 15 significantly between patients and between treatment sites. So an electrode/needle length appropriate to treat a large patient may impact bone during insertion into a small patient. Electrode contact with bone could cause injury to the patient and/or it could distort the electrode array and effect safety and efficacy of the treatment. It is therefore desirable to provide a means for adjusting the depth of electrode/needle penetration based on the treatment site and patient
 20 anatomy.

In the present invention, an adjustable ring 240 over the distal tip of the present invention modifies the electrode/needle penetration depth. The ring can be adjusted axially relative to the cartridge 200 tip so that the length of the ring that extends beyond the distal tip of the device reduces the length of electrode/needle that penetrate into the patient. The specific embodiment
 25 illustrated in Figures 1-5 utilizes a diamond shaped ring that snaps into discrete axial positions. To modify its position, the major axis of the diamond shaped ring is compressed causing the minor axis to expand and release the ring from the cartridge. Another suitable embodiment is a ring that is threaded onto the cartridge tip and can be adjusted by threading the ring back and forth on the cartridge. This embodiment allows for a continuous number of depth adjustment
 30 positions.

Automatic/Passive Release of Trigger Safety

- Inadvertent release of the primed insertion and injection spring mechanisms can result in injury, loss of therapeutic agent and/or damage to the device. It is therefore desirable to provide a safety system to prevent accidental release of the spring mechanisms. It is preferable that such a safety system prevent accidental release of the spring mechanisms due to external forces such as vibration and impact. Additionally, the operator may inadvertently activate the treatment sequence when handling the device, so it is also preferable that the safety system prevent activation of the treatment sequence unless the device is properly applied to the treatment site. Proper placement at the treatment site can also affect treatment efficacy. For instance, the device is desirably applied to the treatment site with adequate force to assure that the electrodes/needle penetrate into the tissue to the full-prescribed depth. Preferably the safety system is automatically and passively deactivated when the device is applied to the treatment site with adequate force. Automatic and passive disablement of the safety system does not require a separate operator step. In addition to simplifying the procedure, automated/passive safety disablement also eliminates the possible failure mode of not deactivating the safety system.

- To ensure that the electrodes/needle penetrate into the tissue to the full-prescribed depth, the minimum force with which the device is applied to the treatment site (the "application force") will exceed the force necessary to insert the electrodes/needle (the "electrode insertion force"). The electrode insertion force is dependent upon several variables, which are disclosed in detail herein below. By way of example, a typical electrode insertion force may be 2.5 pounds, therefore, the minimum application force would be 2.5 pounds. Preferably, a margin of safety would be added to the insertion force so the application force would be between 3.5 and 5.0 pounds. Preferably the required application force will not exceed a force that the operator can comfortably apply to the treatment site.

- A preferred embodiment of the disclosed safety system is herein described. Within the applicator 100 at least one mechanical stop 140 physically prevents the latches 112, 122 from disengaging from the insertion 120 and injection 110 spring mechanisms. The connection between the applicator trigger and the pulse generator is maintained open by an electronic switch 142 thereby preventing accidental activation of the treatment sequence. The internal mechanisms of the applicator float axially within an outer housing 102 and are maintained in an extended position by a spring 144 acting between the internal applicator and the external housing. The spring is equal to the preferred application force. When the device is applied to

the treatment site with adequate pressure to overcome the spring force, the internal applicator is repositioned within the outer housing 102. In this position the safety systems are disabled. The stop 140 is repositioned relative to the latches and no longer prevents the latches from disengaging from the insertion and injection spring mechanisms. Furthermore the electronic switch 142 contacts the outer housing and is closed allowing the trigger to communicate with the pulse generator and initiate the treatment sequence.

Electrode Array Insertion Spring Force/Rate

Electrode insertion mechanisms require sufficient force to rapidly penetrate the skin and implant the electrodes into the muscle. Rapid insertion can reduce tenting of the skin at the insertion site and thereby reduce deflection of the electrode or needle. Electrode deflection may distort the electrode array and effect treatment efficacy and patient safety. Needle distortion may effect co-localization of the agent and electrical fields. So it is desirable to insert the electrodes and needle rapidly to minimize deflection. Additionally rapid electrode/needle insertion reduces patient discomfort. The energy storage and discharge characteristics of spring-based mechanisms are well suited to enable rapid deployment of electrodes and injection needles into tissue with minimal distortion.

Several variables influence the spring force necessary for rapid intramuscular electrode insertion including electrode diameter, number of electrodes, spacing between electrodes and electrode tip geometry. For intramuscular EMTAD, common electrode diameters range from 0.25 mm to 1.50 mm and typical electrode array configurations contain from 2 to 7 electrodes. The force required to insert the electrode arrays within these ranges is proportional to both the electrode diameter and to the number of electrodes. For instance increasing the electrode diameter and/or increasing the number of electrodes results in an increase of the minimum required insertion force. Electrode spacing on the other hand is inversely proportional to the spacing between electrodes. Due to the interaction of tissue that is displaced as the electrode is inserted smaller electrode spacing result in higher insertion force. Typical EMTAD devices, incorporating arrays of penetrating electrodes utilize an intra-electrode spacing at least 10 times greater than the diameter of the electrodes comprising the array and more commonly 15-20 times greater. Within this range there is little interaction of displaced tissue and therefore electrode spacing has minimal effect on the insertion force. Cutting electrode tip geometry is preferred to minimize insertion force. Blunt and dilating tip geometry requires increased insertion force.

- Experiments are carried out to determine minimum spring force/rate necessary for rapid percutaneous intramuscular electrode implantation. A selection of electrode arrays appropriate for intramuscular application of EMTAD and with cutting tip electrodes is evaluated. Each electrode array is implanted into a porcine model and the minimum spring force necessary to
- 5 rapidly penetrate the cutaneous tissue and implant the electrode array without significant distortion is determined. Because of the force exerted by a spring decreases as the energy is released from the spring two results are given. The first is the force at the beginning of the spring stroke and represents the minimum force necessary to penetrate the cutaneous tissue. The second is the force at the end of the spring stroke and represents the minimum force necessary to
- 10 implant the electrode array through the sub cutaneous and muscle tissue. Because the forces are dependent upon the electrode diameter and the number of electrodes the results are given as a ratio of force to total cross-sectional area of the electrodes in the array. The results indicate that a minimum of 1000 pounds of force per square inch of cross-sectional area of electrodes at the beginning of the implant stroke and a minimum of 500 pounds of force per square inch of cross-sectional area of electrodes at the end of the implant stroke is required to implant the electrodes.
- 15 In order to assure consistent and reliable deployment of the electrodes an initial implant force of at least 2000 pounds per square inch of electrode cross sectional area and a terminal implant force of at least 750 pounds of force per square inch of cross-sectional area of electrodes is preferred.
- 20 By way of example, an array comprised of 4 electrodes, each with a diameter of 0.02 inches would have a total cross-sectional area of approximately 0.00125 square inches. Thus a mechanism for deployment of our example array would require a minimum force of 1.25 pounds to achieve insertion and more preferably a force of at least 2.50 pounds.
- 25 In embodiments where the spring mechanisms are manually primed, it is preferable to limit the force of the springs so that the operator can comfortably prime the springs. A preferred limit for spring priming is less than 15 pounds force. For embodiments where each spring mechanism is primed separately the maximum force for a spring is 15 pounds. However for those embodiments where the insertion and injection spring mechanisms are primed simultaneously the combined spring force preferably will not exceed 15 pounds.

Agent Administration Spring Force/Rate

Several variables affect the force necessary to administer the therapeutic agent. These variables include, agent viscosity, cross-sectional area of the syringe, needle gauge, cross-sectional area of orifice(s), and tissue density. For parameters typical of intramuscular EMTAD

5 the minimum spring force necessary to administer the therapeutic agent is 0.25 pounds. Preferably the injection spring force is between 1 and 10 pounds.

Although the functional characteristics and cost effectiveness of the injection spring mechanism makes it preferable overall, the impact of the drive mechanism on the syringe plunger can create a "water hammer" effect. The force wave generated from the impact can

10 travel through the agent within the syringe and result in damage to the syringe or needle. In particular, standard plastic needle hubs may crack or split causing the agent to leak before it is completely administered. It is therefore desirable to damp the impact energy of the drive mechanism without affecting the force/rate of agent injection.

There are several means to damp the impact energy of the drive mechanism. One such

15 means is to position an energy absorbing material 118 between the syringe plunger 302 and drive mechanism 116. Appropriate energy absorbing materials include but are not limited to elastomers such as silicone and polyurethane and closed-cell foams. Another suitable means to absorb the impact is gas/fluid dampening to slow the rate of the drive mechanism. Such an apparatus requires that at least a portion of the injection drive mechanism displace a gas or fluid

20 through a small bleed hole in order to move forward. Preferably the gas is air and the bleed hole is tuned so that the dampening or is less than the dampening produced from administering the agent through the injection needle. In such a case, the gas dampening will only effect the rate of the drive mechanism until it contacts the syringe at which point the dampening produced from administering the agent through the injection needle will be the limiting factor affecting agent

25 administration.

Automatic/Passive Stick Prevention

Post treatment the electrodes and injection needle present a hazard for needle sticks and transfer of blood borne pathogens. Therefore it is desirable that the device includes integral stick

30 protection. Moreover it is desirable that the stick protection is both automatic and passive. Automatic stick protection will eliminate possible injury when manually deploying the stick protection and it also eliminates the possible failure mode of not deploying the stick protection.

Preferably, upon activation the stick protection includes a means for locking in place to prevent possible someone from defeating the stick protection once it has deployed.

One preferred embodiment of an integral automatic locking stick protection is presented. However one skilled in the art will appreciate that other embodiments that can achieve the same
5 objective. The specific embodiment herein described utilizes a stick shield 250 integral to the cartridge that automatically extends over the electrodes/needle as they are removed from the patient. A compression spring 252 within the cartridge is positioned proximal to the stick shield between the stick shield and the electrode hub 220. As the electrode hub advances distally during electrode/needle insertion the spring is compressed. When the electrodes/needle are
10 removed post treatment from the patient, the spring extends and extends the stick shield distally over the electrodes and needle. As the shield is completely extended over the electrodes and needle cantilevered tabs on the stick shield snap into corresponding grooves in the collar 210 thereby locking the shield in the extended position.

15 Single Use

Users may attempt to reuse the single use cartridge to save costs or to apply an off label agent. Reusing the cartridge may affect the safety and efficacy of the treatment. For instance coatings on the electrodes that may be utilized to assure biocompatibility may not withstand multiple uses so the treatment may produce a toxic result in the patient. Additionally, sterility of
20 a reused device cannot be assured. It is therefore desirable to include features in the device that prevent reuse.

The device herein described includes three features that prevent reuse. The stick shield 250 locks in an extended position preventing the electrodes and needle from being inserted into the patient. The syringe is permanently attached to the cartridge when it is inserted, so the
25 syringe cannot be detached to reload it with the agent. Finally, after electrode insertion the cartridge hub/collar configuration is fixed with the hub inserted into the collar. In this configuration the cartridge will not prime the insertion and injection spring mechanisms. Also in this configuration the cartridge identification contacts in the applicator will not communicate with the cartridge so the control system will not recognize the cartridge and will prevent
30 treatment.

Those skilled in the art will recognize that there are other suitable means for preventing reuse. One such method is to incorporate a fuse into the cartridge and apply a signal from the

pulse generator that blows the fuse at the end of the treatment. Another such means is to identify each cartridge with a unique serial number that is read by the applicator. The pulse generator would store the serial numbers and not apply treatments through cartridges whose serial numbers have already been read and stored.

5

Manufacturability

In order to be well suited for commercial application, the manufacturing costs of a single-use cartridge should be as low as possible. In addition, when applying EMTAD multiple electrode array configurations may be required to deliver a range of doses prescribed for a given agent. One method of reducing manufacturing costs while producing multiple array configurations is to utilize many of the same components in the multiple cartridge configurations. This approach will reduce costs including but not limited to tooling costs, inventory costs, quality control costs and handling costs.

In the specific embodiment illustrated in Figure 5, the electrode array configuration is modified by changing the geometry of only the electrodes 260. A bend 262 near the distal end of the electrode changes the relative position of the penetrating end of the electrodes within the cartridge and thus changes the array configuration. The cartridge components are designed to accept multiple electrode geometries and therefore can be utilized in multiple electrode array configurations. Additionally the cartridge components have been designed to snap together and utilize the bend in the electrode to securely capture the electrodes between the cartridge components. This approach further reduces fabrication costs by elimination more costly joining techniques such as adhesive joints, solvent bonding, insert molding and ultrasonic welding.
